ADAPTIVE BOUNDARY ELEMENT METHODS FOR THE
COMPUTATION OF THE ELECTROSTATIC CAPACITY ON
COMPLEX POLYHEDRA

TIMO BETCKE, ALEXANDER HABERL, AND DIRK PRAETORIUS

Abstract. The accurate computation of the electrostatic capacity of three dimensional objects is a fascinating benchmark problem with a long and rich history. In particular, the capacity of the unit cube has widely been studied, and recent advances allow to compute its capacity to more than ten digits of accuracy. However, the accurate computation of the capacity for general three dimensional polyhedra is still an open problem. In this paper, we propose a new algorithm based on a combination of ZZ-type a posteriori error estimation and effective operator preconditioned boundary integral formulations to easily compute the capacity of complex three dimensional polyhedra to 5 digits and more. While this paper focuses on the capacity as a benchmark problem, it also discusses implementational issues of adaptive boundary element solvers, and we provide codes based on the boundary element package Bempp to make the underlying techniques accessible to a wide range of practical problems.

1. Introduction

1.1. The capacity problem. The capacity $\text{Cap}(\Omega)$ of an isolated conductor $\Omega \subset \mathbb{R}^3$ measures its ability to store charges. It is defined as the ratio of the total surface equilibrium charge relative to its surface potential value [Kel67]. To compute the capacity, we therefore need to solve the following exterior Laplace problem for the equilibrium potential $u$ with unit surface value:

$$
\begin{align*}
-\Delta u &= 0 \quad \text{in } \mathbb{R}^3 \setminus \overline{\Omega}, \\
    u &= 1 \quad \text{on } \Gamma := \partial \Omega, \\
    |u(x)| &= O\left(|x|^{-1}\right) \quad \text{as } |x| \to \infty.
\end{align*}
$$

The total surface charge of an isolated conductor is then given by Gauss’ law as

$$
\text{Cap}^*(\Omega) = -\epsilon_0 \int_{\Gamma} \frac{\partial u}{\partial \nu}(x) \, d\Gamma(x).
$$

Here, $\nu(x)$ is the outward pointing normal vector for $x \in \Gamma$, and $\epsilon_0$ is the electric constant with value $\epsilon_0 \approx 8.854 \times 10^{-12} \text{ F/m}$. In the rest of the paper, we will use the normalized capacity $\text{Cap}(\Omega) = \frac{1}{4\pi} \int_{\Gamma} \frac{\partial u}{\partial \nu} \, d\Gamma$, which is commonly used in the literature.

1.2. State of the art. Analytic expressions of the capacity in 3D are only known for very few simple domains, such as a sphere with radius $r$, for which $\text{Cap}(\Omega) = r$. Moreover, computing the capacity to high accuracy even for simple shapes such as the unit cube is exceedingly difficult as it involves the solution of the exterior Laplace problem [1].
for (possibly) non-smooth domains. This is very different from the 2D case, where techniques such as fast Schwarz-Christoffel maps \cite{DT02,BT03} allow the computation of the logarithmic capacity to many digits of accuracy even on complex domains.

Nevertheless, there have been a range of interesting developments over the years to compute the capacity in three dimensions. A frequently used benchmark example is the capacity of the unit cube, which we will also use in this paper to compare our results to existing methods. An early bound for the normalized capacity $C$ of the unit cube was published by Pólya already in 1947 \cite{Póly47} who estimated that

$$0.62033 < C < 0.71055.$$ 

Over the years, several improvements have been made, some of which are summarized in \cite{HMW10}. In that paper, techniques based on random walks are used to compute the capacity as 0.66067813 with an error believed to be in the order of $\pm 1.01 \times 10^{-7}$. In 2013, \cite{HP13} improved the existing computations by using Nyström methods and multilevel solvers to 0.66067815409957 with an error in the order of $10^{-13}$.

Adaptive boundary element computations for the capacity are not completely new. For example, in \cite{Rea97} a pre-chosen anisotropic refinement towards the edges is used together with an extrapolation technique to compute the capacity of the unit cube to around six digits of accuracy. However, the computations in that paper are simplified by exploiting the special symmetry of the cube and do not generalize to arbitrary polyhedra. Moreover, \cite{Rea97} briefly mentions also an adaptive refinement strategy that is based on refining elements with large charge contributions.

### 1.3. Contributions of the present work.

In this paper, we present a black-box method for capacity computations of polyhedra in three dimensions, which achieves a similar accuracy of order $10^{-6}$ for the unit cube. Our method is based on an adaptive boundary element computation, which uses a ZZ-type a posteriori error estimator to steer the mesh-refinement in combination with a suitable operator preconditioning. Our ansatz is completely generic in that the adaptive refinement strategy works for any type of polyhedron and quickly generates meshes that compute the capacity for a given shape to several digits of accuracy.

### 1.4. Main results in a nutshell.

A boundary integral formulation for the computation of the capacity can be derived by considering Green’s representation theorem and noting that the exterior Laplace double-layer potential is zero for constant densities. We hence obtain a representation of the solution $u$ of (1) as

$$u(x) = \int_{\Gamma} G(x, y) \phi(y) d\Gamma(y) \quad \text{for all } x \in \mathbb{R}^3 \setminus \overline{\Omega},$$

where $\phi := -\partial u/\partial \nu$ is the (negative) normal derivative of the exterior solution $u$ and $G(x, y) := \frac{1}{4\pi |x-y|}$ is the Green’s function of the 3D Laplacian. Taking boundary traces, the right-hand side of (3) gives rise to the Laplace single-layer integral operator $V$, and we arrive at the boundary integral equation of the first kind

$$1 = \int_{\Gamma} G(x, y) \phi(y) d\Gamma(y) =: [V \phi](x) \quad \text{for all } x \in \Gamma.$$ 

Then,

$$\text{Cap}(\Omega) = \frac{1}{4\pi} \int_{\Gamma} \phi \, d\Gamma.$$ 

$$\text{Cap}(\Omega) = \frac{1}{4\pi} \int_{\Gamma} \phi \, d\Gamma.$$
The challenge is to accurately compute the solution $\phi$ of \ref{eq:laplace} close to edges and corners of a polyhedron. High-order collocation or Nyström methods work well for smooth obstacles, but are difficult to apply to surfaces with corners or edges. Therefore, we propose to use a Galerkin boundary element method (BEM) combined with a posteriori error estimation and adaptive mesh-refinement. The proposed algorithm is of the common type

\[
\text{solve} \quad \rightarrow \quad \text{estimate} \quad \rightarrow \quad \text{mark} \quad \rightarrow \quad \text{refine}
\]

and generates a sequence of successively refined triangulations $\mathcal{T}_\ell$ and corresponding Galerkin approximations $\Phi_\ell \approx \phi$ such that $\text{Cap}_\ell(\Omega) := \frac{1}{2\pi} \int_{\Gamma} \Phi_\ell d\Gamma$ converges to $\text{Cap}(\Omega)$ at the optimal algebraic rate. The mathematical foundation of such algorithms for BEM has recently been derived in \cite{FKMP13, Gan13, FFK14, FFK15}. One novelty in the present paper is that we combine adaptivity with an effective preconditioning strategy.

We assume that $\mathcal{T}_\ell$ is a triangulation of $\Gamma$ into plane surface triangles. Let $\mathcal{T}_\ell^{\text{dual}}$ be the induced dual grid; see Figure \ref{fig:dualgrid}. Let $S^1(\mathcal{T}_\ell)$ be the $\mathcal{T}_\ell$-piecewise affine globally continuous functions and $\mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$ be the $\mathcal{T}_\ell^{\text{dual}}$-piecewise constant functions on $\Gamma$. It is known \cite{SW98, Hip06} that one can use the (regularized) discrete hypersingular integral operator $D^{\text{reg}}_\ell$ on $S^1(\mathcal{T}_\ell)$ to effectively precondition the discrete weakly-singular integral operator $V^{\text{dual}}_\ell$ on $\mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$. The Galerkin approximation $\Phi^{\text{dual}}_\ell \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$ is obtained as

\[
\Phi^{\text{dual}}_\ell = D^{\text{reg}}_\ell \hat{\Phi}_\ell, \quad \text{where } \hat{\Phi}_\ell \text{ solves the preconditioned system } (V^{\text{dual}}_\ell D^{\text{reg}}_\ell \hat{\Phi}_\ell) = 1. \quad (6)
\]

Having computed $\Phi^{\text{dual}}_\ell$, we use that each vertex $z$ of $\mathcal{T}_\ell$ corresponds to precisely one dual cell $T^{\text{dual}}_z \subset \mathcal{T}_\ell^{\text{dual}}$. To steer the mesh-refinement, we compute the ZZ-type error indicators

\[
\eta_\ell(T) := \text{diam}(T)^{1/2} \| \Phi^{\text{dual}}_\ell - I_\ell \Phi^{\text{dual}}_\ell \|_{L^2(T)} \quad \text{for all } T \in \mathcal{T}_\ell, \quad (7)
\]

where $I_\ell \Phi^{\text{dual}}_\ell \in S^1(\mathcal{T}_\ell)$ is the unique function with $I_\ell \Phi^{\text{dual}}_\ell(z) = \Phi^{\text{dual}}_\ell|_{T^{\text{dual}}_z}$ for all vertices $z$ of $\mathcal{T}_\ell$. We refer to \cite{ZZ77, Roc94, BC02} for ZZ-type estimators for FEM and to \cite{FFKP14} for first ideas for 2D BEM. The local contributions $\eta_\ell(T)$ are then used to mark elements for refinement. An improved triangulation $\mathcal{T}_{\ell+1}$ is obtained from $\mathcal{T}_\ell$ by refining (essentially) these marked elements.

The mentioned results on adaptive BEM \cite{FKMP13, Gan13, FFK14, FFK15} consider residual error estimators, which provide more mathematical structure than the heuristical ZZ-error estimator \ref{eq:zz-est}. However, we note that the evaluation and integration of the BEM residual is usually more costly than the computation of the BEM solution \ref{eq:bem}, while the ZZ-error estimator comes essentially at no cost.

The striking advantage of the proposed strategy is that both discrete integral operators $D^{\text{reg}}_\ell$ as well as $V^{\text{dual}}_\ell$ can effectively be treated as follows: Let $\mathcal{T}^{\text{bary}}_\ell$ be the barycentric refinement of $\mathcal{T}_\ell$. We then build the discrete weakly-singular integral operator $V^{\text{bary}}_\ell$ with respect to $\mathcal{P}^0(\mathcal{T}^{\text{bary}}_\ell)$. Both operators $D^{\text{reg}}_\ell$ and $V^{\text{dual}}_\ell$ can be obtained by (sparse) projection operators applied to $V^{\text{bary}}_\ell$; see Section \ref{sec:bem}. Since the computation of $\hat{\Phi}_\ell$ of $\Phi^{\text{dual}}_\ell$ by iterative solvers relies only on matrix-vector products, we altogether assemble and store only $V^{\text{bary}}_\ell$. Finally, since the number of elements satisfies $\# \mathcal{T}^{\text{bary}}_\ell = 6 \# \mathcal{T}_\ell$, preconditioning and adaptivity do not lead to any significant overhead of the overall method.

## 2. Preconditioned Adaptive BEM for Laplace Problems

In this section, we describe the numerical implementation of the preconditioned boundary integral equation \ref{eq:bem} and the corresponding ZZ-type error estimator. This forms the basis for our adaptive capacity algorithm described in Section \ref{sec:adaptivity}.
Figure 1. Construction of the dual mesh $\mathcal{T}_\ell^{\text{dual}}$ (left) and the barycentric refinement $\mathcal{T}_\ell^{\text{bary}}$ (right) for a given mesh $\mathcal{T}_\ell$ indicated by the thick edges (left and right). Each (polygonal) dual element $T^{\text{dual}} \in \mathcal{T}_\ell^{\text{dual}}$ (left, gray) corresponds to one node of $\mathcal{T}_\ell$. Each (triangular) element $T^{\text{bary}} \in \mathcal{T}_\ell^{\text{bary}}$ belongs to precisely one triangle $T \in \mathcal{T}_\ell$.

Figure 2. Approximation error of the BEM for a Laplace–Dirichlet problem on the unit cube with continuous, piecewise linear basis functions on the primal mesh (left) and piecewise constant basis functions on the dual grid (right).

The standard way of approximating Neumann data on polyhedral boundaries is the approximation through piecewise constant basis functions on the primal grid, given the discontinuity of Neumann data across edges. Here, we choose a different approximation space, namely the space of piecewise constant functions on the dual grid. The advantage is that this space admits a stable duality pairing with continuous, piecewise affine functions on the primal grid, allowing us to use efficient operator preconditioning techniques based on the duality of the single-layer and hypersingular boundary operator, while at the same time making it possible to apply a ZZ-type error estimator as shown below.

Moreover, even though the piecewise constant basis on the dual grid is locally continuous across edges, it recovers optimal $h$-uniform convergence to solutions of Laplace–Dirichlet problems. An example is given in Figure 2 which demonstrates the $h$-convergence in the dual basis to the Neumann data of a Laplace–Dirichlet problem on the unit cube with analytically known solution. The shown error is the relative $L^2$-error for the piecewise smooth Neumann data. The convergence is linear.
While a complete convergence analysis in the dual basis is beyond the merit of this paper, a simple heuristic argument is the following: The dual basis is continuous in a radius of diameter $h$ across an edge, and discontinuous globally. Hence, locally around an edge we have an error contribution that decreases with order $h$, while not propagating beyond due to the discontinuity of the basis. We therefore expect to recover the optimal convergence order $h$ for the $L^2$-error.

**2.1. Triangulations.** Throughout, let $\Omega \subset \mathbb{R}^3$ be a bounded polyhedral domain with closed boundary $\Gamma$. We consider conforming triangulations $\mathcal{T}_\ell = \{T_{\ell,1}, \ldots, T_{\ell,N_\ell}\}$ of $\Gamma$ into $N_\ell = \#\mathcal{T}_\ell$ plane (closed) surface triangles $T_{\ell,j} \in \mathcal{T}_\ell$. Let $N_\ell = \{z_{\ell,1}, \ldots, z_{\ell,M_\ell}\}$ be the set of vertices of $\mathcal{T}_\ell$, which contains the $M_\ell = \#N_\ell$ vertices.

To obtain the dual mesh $\mathcal{T}_\ell^{\text{dual}}$, we connect the center of gravity of each element $T_{\ell,j} \in \mathcal{T}_\ell$ with the midpoints of its edges. These lines define $M_\ell$ non-degenerate closed polygons $T_{\ell,j}^{\text{dual}}$, which are collected in the dual mesh $\mathcal{T}_\ell^{\text{dual}} = \{T_{\ell,1}^{\text{dual}}, \ldots, T_{\ell,M_\ell}^{\text{dual}}\}$, where $\#\mathcal{T}_\ell^{\text{dual}} = M_\ell = \#N_\ell$. Note that each cell $T_{\ell,j}^{\text{dual}} \in \mathcal{T}_\ell^{\text{dual}}$ contains precisely one node $z_{\ell,j} \in N_\ell$ in its interior, and we use the according numbering of $\mathcal{T}_\ell^{\text{dual}}$ and $N_\ell$, i.e., $z_{\ell,j} \in \text{interior}(T_{\ell,j}^{\text{dual}})$ for all $j = 1, \ldots, M_\ell$; see Figure 4 (left).

Finally, we refine each element $T_{\ell,j} \in \mathcal{T}_\ell$ into six triangles by connecting the center of gravity of $T_{\ell,j}$ with the midpoints of its edges as well as its vertices. This gives rise to the barycentric refinement $T_{\ell,j}^{\text{bary}} = \{T_{\ell,1}^{\text{bary}}, \ldots, T_{\ell,bN_\ell}^{\text{bary}}\}$. We note that $\#T_{\ell,j}^{\text{bary}} = 6 \#T_{\ell} = 6 N_\ell$. Moreover, each element $T_{\ell,j} \in \mathcal{T}_\ell$ and $T_{\ell,j}^{\text{dual}} \in \mathcal{T}_\ell^{\text{dual}}$ is the union of elements in $T_{\ell,j}^{\text{bary}}$, i.e.,

$$T = \bigcup \{T^{\text{bary}} \in T_{\ell,j}^{\text{bary}} : T^{\text{bary}} \subset T\} \quad \text{for all } T \in \mathcal{T}_\ell \cup \mathcal{T}_\ell^{\text{dual}},$$

see Figure 4 (right). In other words, $T_{\ell,j}^{\text{bary}}$ is the coarsest common refinement of $T_\ell$ and $\mathcal{T}_\ell^{\text{dual}}$ into plane surface triangles.

**2.2. Discrete function spaces.** In this section, we collect the discrete spaces of functions $\Gamma \to \mathbb{R}$, which are employed below.

On $\mathcal{T}_\ell^{\text{dual}}$, we consider the space $P^0(\mathcal{T}_\ell^{\text{dual}})$ of $\mathcal{T}_\ell^{\text{dual}}$-piecewise constant functions. We choose the basis $\{\chi_{\ell,1}^{\text{dual}}, \ldots, \chi_{\ell,M_\ell}^{\text{dual}}\}$ consisting of characteristic functions, i.e., $\chi_{\ell,j}^{\text{dual}}(x) = 1$ on $T_{\ell,j}^{\text{dual}}$ and zero otherwise.

On $\mathcal{T}_\ell$, we consider the space $S^1(\mathcal{T}_\ell)$ of $\mathcal{T}_\ell$-piecewise affine functions, which are globally continuous. We choose the usual nodal basis $\{\varphi_{\ell,1}, \ldots, \varphi_{\ell,M_\ell}\}$, which consists of the hat functions characterized by $\varphi_{\ell,i}(z_{\ell,i}) = 1$ and $\varphi_{\ell,i}(z_{\ell,j}) = 0$ for $i \neq j$.  

![Figure 3. For each triangle $T \in \mathcal{T}_\ell$, there is one fixed reference edge, indicated by the double line (left, top). Refinement of $T$ is done by bisecting the reference edge, where its midpoint becomes a new vertex of the refined triangulation $\mathcal{T}_{\ell+1}$. The reference edges of the son triangles are opposite to this newest vertex (left, bottom). To avoid hanging nodes, one proceeds as follows: We assume that certain edges of $T$, but at least the reference edge, are marked for refinement (top). Using iterated newest vertex bisection, the element is then split into 2, 3, or 4 son triangles (bottom).](image-url)
On $\mathcal{T}_\ell^{\text{bary}}$, we consider the space $\mathcal{P}^0(\mathcal{T}_\ell^{\text{bary}})$ of $\mathcal{T}_\ell^{\text{bary}}$-piecewise constant functions. Again, we choose the basis $\{\chi_{\ell,i}^{\text{bary}}, \ldots, \chi_{\ell,N\ell}^{\text{bary}}\}$ consisting of characteristic functions, i.e., $\chi_{\ell,j}^{\text{bary}}(x) = 1$ on $T_{\ell,j}^{\text{bary}}$ and zero otherwise.

### 2.3. Galerkin discretization of the Laplace integral equation.

For general $f \in H^{1/2}(\Gamma)$ (and $f = 1$ for the capacity problem), we consider the weakly-singular boundary integral equation

$$V\phi(x) := \frac{1}{4\pi} \int_{\Gamma} \frac{\phi(y)}{|x - y|} \, d\Gamma(y) = f(x) \quad \text{for all } x \in \Gamma, \quad (8)$$

where $V : H^{-1/2}(\Gamma) \rightarrow H^{1/2}(\Gamma)$ is the Laplace single-layer integral operator.

We refer, e.g., to the monographs [McL00, HW08, Ste08, SS11, GS18] for the following facts on the functional analytic framework:

Let $(g, \psi)_\Gamma := \int_{\Gamma} g(x) \psi(x) \, d\Gamma(x)$ be the $L^2(\Gamma)$-based duality pairing between functions $g \in H^{1/2}(\Gamma)$ and $\psi \in H^{-1/2}(\Gamma)$. We can reformulate (8) as variational problem in the form

$$\langle V\phi, \psi \rangle_\Gamma = \langle f, \psi \rangle_\Gamma \quad \text{for all } \psi \in H^{-1/2}(\Gamma). \quad (9)$$

From the ellipticity of $V$ in $H^{-1/2}(\Gamma)$ with respect to $\langle \cdot, \cdot \rangle_\Gamma$, the unique solvability of (9) follows by the Lax–Milgram lemma. In particular, we note that $\| \psi \| := \langle V\psi, \psi \rangle_\Gamma^{1/2} \simeq \| \psi \|_{H^{-1/2}(\Gamma)}$ defines the equivalent energy norm on $H^{-1/2}(\Gamma)$. Here and throughout, $\lesssim$ abbreviates $\leq$ up to some generic multiplicative constant, and $\simeq$ abbreviates that both estimates $\lesssim$ and $\gtrsim$ hold.

Since $\mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}}) \subset H^{-1/2}(\Gamma)$, we can discretize (9) by a Galerkin discretization [Ste08, SS11]: Find $\Phi^\text{dual}_\ell \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$ such that

$$\langle V\Phi^\text{dual}_\ell, \Psi^\text{dual}_\ell \rangle_\Gamma = \langle f, \Psi^\text{dual}_\ell \rangle_\Gamma \quad \text{for all } \Psi^\text{dual}_\ell \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}}). \quad (10)$$

Again, unique solvability of (10) follows by the Lax–Milgram lemma. Moreover, the latter is equivalent to the linear system of equations

$$V^\text{dual}_\ell \mathbf{x}_\ell = \mathbf{f}^\text{dual}_\ell \quad (11)$$

with the symmetric and positive definite matrix $V^\text{dual}_\ell \in \mathbb{R}^{M_\ell \times M_\ell}$ and given right-hand side $\mathbf{f}^\text{dual}_\ell \in \mathbb{R}^{M_\ell}$ defined as $V^\text{dual}_\ell[i,j] = \langle V\chi^\text{dual}_{\ell,i}, \chi^\text{dual}_{\ell,j} \rangle_\Gamma$ and $\mathbf{f}^\text{dual}_\ell[i] = \langle f, \chi^\text{dual}_{\ell,i} \rangle_\Gamma$. Then, the unique solution $\Phi^\text{dual}_\ell \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$ of (10) satisfies $\Phi^\text{dual}_\ell = \sum_j \mathbf{x}_\ell[j] \chi^\text{dual}_{\ell,j}$, where $\mathbf{x}_\ell \in \mathbb{R}^{M_\ell}$ is the unique solution to the linear system (11).

### 2.4. ZZ-type a posteriori error estimation.

Having computed the Galerkin solution $\Phi^\text{dual}_\ell \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$, we define $I_\ell \Phi^\text{dual}_\ell := \sum_j \mathbf{x}_\ell[j] \varphi_{\ell,j} \in \mathcal{S}^1(\mathcal{T}_\ell)$ as well as the ZZ-type error indicators (7) for all $T \in \mathcal{T}_\ell$. For model problems with known solution, our numerical experiments led to the evidence that

$$\sum_{T \in \mathcal{T}_\ell} \eta_T(T)^2 = \| h^{1/2}_\ell (1 - I_\ell) \Phi^\text{dual}_\ell \|_{L^2(\Gamma)}^2 \simeq \| \phi - \Phi^\text{dual}_\ell \|_\Gamma^2 \simeq \| \phi - \Phi^\text{dual}_\ell \|_{H^{-1/2}(\Gamma)}^2, \quad (12)$$

where $h_\ell : \Gamma \rightarrow \mathbb{R}$ is the $T_\ell$-piecewise mesh-size function $h_\ell|_T = \text{diam}(T)$. A thorough mathematical proof goes beyond the scope of the present work. We note that the efficiency estimate $\lesssim$ can be obtained with the scaling techniques from [FFKP14], while the more important reliability estimate $\gtrsim$ remains open.
2.5. A generic adaptive strategy. With the ZZ-type error estimator at hand, we consider the following generic adaptive algorithm, which locally adapts the primal mesh $\mathcal{T}_t$, while the Galerkin approximations $\Phi_{t,\ell}^{\text{dual}}$ are computed on the corresponding dual mesh $\mathcal{T}_t^{\text{dual}}$. For the local mesh-refinement, we employ 2D newest vertex bisection (NVB); see, e.g., [KPP13, Sto07] and Figure 3 for some illustration. We note that NVB provides rich mathematical structure and, in particular, guarantees that all adaptive meshes are conforming and uniformly shape regular (i.e., generated triangles $T$ cannot deteriorate).

Algorithm 1. Input: Initial conforming triangulation $\mathcal{T}_0$ of $\Gamma$ into plane surface triangles, adaptivity parameters $0 < \theta \leq 1$ and $C_{\text{mark}} \geq 1$.

Adaptive loop. Iterate the following steps (i)–(iv) for all $\ell = 0, 1, 2, \ldots$:

(i) Build the dual mesh $\mathcal{T}_\ell^{\text{dual}}$ and compute the solution $\Phi_{\ell,1}^{\text{dual}} \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$ of (10).

(ii) Compute the local contributions $\eta(T)$ from (7) for all $T \in \mathcal{T}_\ell$.

(iii) Determine a set of, up to the multiplicative constant $C_{\text{mark}}$, minimal cardinality, which satisfies the Dörfler marking criterion $[\text{Dör96}]$

\[ \theta \sum_{T \in \mathcal{T}_\ell} \eta(T)^2 \leq \sum_{T \in \mathcal{M}_\ell} \eta(T)^2, \]

i.e., the local contributions associated with $\mathcal{M}_\ell$ control a fixed percentage of $\eta^2$.

(iv) Use NVB to create the coarsest conforming triangulation $\mathcal{T}_{\ell+1} := \text{refine}(\mathcal{T}_\ell, \mathcal{M}_\ell)$, where all marked elements $T \in \mathcal{M}_\ell$ have been bisected.

Output: Sequence of successively refined triangulations $\mathcal{T}_\ell$ as well as corresponding Galerkin solutions $\Phi_{\ell,\ell}^{\text{dual}} \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$ and ZZ-type error estimators $\eta_{\ell}$. □

The code of a Python implementation of Algorithm 1 based on the Bempp library is given in Appendix B. Similar algorithms driven by computationally expensive residual error estimators have been mathematically analyzed in recent years [Gan13, FKMP13, FFK+14, FFK+15, FHP18]. We refer to the appendix for details on available results.

Remark 2. In practice, the linear system (11) is solved iteratively. In our implementation, the preconditioned GMRES solver is stopped, if the iterates $\Phi_{\ell,k}^{\text{dual}} \approx \Phi_{\ell}^{\text{dual}}$ satisfy that $\| \Phi_{\ell,k-1}^{\text{dual}} - \Phi_{\ell,k}^{\text{dual}} \| \leq \lambda \eta(T_{\ell,k}^{\text{dual}})$ where $\lambda \approx 10^{-5}$. Here, $\eta(T_{\ell,k}^{\text{dual}})$ denotes the ZZ-error estimator evaluated at the inexact solution $\Phi_{\ell,k}^{\text{dual}}$ instead of the exact Galerkin solution $\Phi_{\ell}^{\text{dual}}$. We refer to the recent work [FHP18] for a thorough mathematical analysis of the stopping criterion.

Remark 3. In the numerical experiments below, we compare our adaptive algorithm (with BEM solution $\Phi_{\ell}^{\text{dual}} \in \mathcal{P}^0(\mathcal{T}_\ell^{\text{dual}})$) with a standard adaptive algorithm (with BEM solution $\Phi_{\ell} \in \mathcal{P}^0(\mathcal{T}_\ell)$ on the primal mesh) driven by a residual error estimator. In order to compute $\Phi_{\ell}^{\text{dual}}$, we assemble the discrete single-layer operator $V_{\ell}^{\text{dual}}$ on $\mathcal{P}^0(\mathcal{T}_\ell)$, which increases the degrees of freedom by a factor 3, the computational costs grow at least by the same factor.

On the other hand, the proposed Algorithm 1 with the ZZ-type error estimator requires to assemble the discrete single-layer operator $V_{\ell}^{\text{bary}}$ on $\mathcal{P}^0(\mathcal{T}_\ell^{\text{bary}})$, which increases the degrees of freedom by a factor 6, but already includes the operator preconditioning; see Section 2.6 for further details. Hence, using a suitable implementation with FMM or H-Matrices, Algorithm 1 with an built-in operator preconditioning just leads to double...
we recognize that we can write the matrix quantities defined as before. The implementation of (14) only requires the assembly of \( \mathbf{M}^{-1} \mathbf{V}^\text{dual} \mathbf{M}^{-1} \mathbf{D}^\text{reg} \mathbf{x}_\ell = \mathbf{M}^{-1} \mathbf{f}_\ell \) (14)

With \( \mathbf{x}_\ell = \mathbf{M}^{-1} \mathbf{D}^\text{reg} \mathbf{x}_\ell \), \( \mathbf{D}^\text{reg}[i, j] = \langle \mathbf{D}^\text{reg} \phi_{\ell,i}, \phi_{\ell,j} \rangle \), \( \mathbf{M}_\ell[i, j]^\top = \langle \phi_{\ell,j}, \chi_{\ell,i}^\text{dual} \rangle \), and the other quantities defined as before. The implementation of (14) only requires the assembly of the matrix \( \mathbf{V}_\ell^\text{bary} \in \mathbb{R}^{N_x \times N_y} \) associated with the single-layer boundary operator on the space \( \mathcal{P}_0(\mathcal{T}_\ell^\text{dual}) \), i.e., \( \mathbf{V}_\ell^\text{bary}[i, j] = \langle \mathbf{V}_\ell^\text{bary} \chi_{\ell,i}^\text{bary}, \chi_{\ell,j}^\text{bary} \rangle \). The matrices \( \mathbf{V}_\ell^\text{dual} \) and \( \mathbf{D}^\text{reg} \) can then be obtained through simple sparse projection operators. To obtain \( \mathbf{V}_\ell^\text{dual} \), we notice that the basis functions \( \chi_{\ell,j}^\text{dual} \) in \( \mathcal{P}_0(\mathcal{T}_\ell^\text{dual}) \) can be written as a linear combinations of the basis \( \chi_{\ell,j}^\text{bary} \) in \( \mathcal{P}_0(\mathcal{T}_\ell^\text{bary}) \). Let \( \mathbf{P}_\ell \in \mathbb{R}^{6N_x \times M_\ell} \) be the sparse matrix that maps coefficients of basis functions in \( \mathcal{P}_0(\mathcal{T}_\ell^\text{dual}) \) to a vector of coefficients of the associated basis functions in \( \mathcal{P}_0(\mathcal{T}_\ell^\text{bary}) \). Then,

\[
\mathbf{V}_\ell^\text{dual} = \mathbf{P}_\ell^\top \mathbf{V}_\ell^\text{bary} \mathbf{P}_\ell.
\]

Similarly, we recognize that we can write

\[
\mathbf{D}^\text{reg} = \sum_{m=1}^{3} \mathbf{Q}_{\ell,m}^\top \mathbf{V}_\ell^\text{bary} \mathbf{Q}_{\ell,m},
\]

where \( \mathbf{Q}_{\ell,m} \in \mathbb{R}^{6N_x \times M_\ell} \) maps coefficient vectors in \( \mathcal{S}^1(\mathcal{T}_\ell) \) to the piecewise constant \( m \)-th component of the corresponding surface curl operator, which can be represented as a linear combination of basis functions in \( \mathcal{P}_0(\mathcal{T}_\ell^\text{bary}) \).
Putting everything into Eq. 14, we obtain the discrete system
\[
M^{-1}_\ell P^T_\ell V^{\text{bary}}_\ell P_\ell M^{-1}_\ell \sum_{m=1}^3 Q^T_\ell,m V^{\text{bary}}_{\ell,m} x_\ell = M^{-T}_\ell g^{\text{dual}}_\ell.
\]
Hence, we only require the assembly of the operator \( V^{\text{bary}}_\ell \) and four matrix-vector products with this operator for each evaluation of the left-hand side. Assuming a fast method with a linear or log-linear complexity for assembly and matrix-vector product, the total cost of the assembly is therefore six times as high as that of the non-preconditioned system and each matrix-vector product about 24 times as expensive as that for a non-preconditioned system. However, we will see later that this preconditioner is very effective and only a small number of matrix-vector products will be required in our numerical experiments. Moreover, the error estimation essentially comes for free as part of this preconditioning strategy; see Section 2.4.

The associated sparse matrix operations with \( P_\ell \) and \( Q_\ell \) are cheap and negligible compared to the evaluation of the integral operators. Using a modern sparse direct solver, also the cost of the LU decomposition of the sparse mass matrix \( M_\ell \) compared to the evaluation of the integral operators. Using a modern sparse direct solver, also the cost of the LU decomposition of the sparse mass matrix \( M_\ell \) and its application is reasonably cheap.

We note that the analysis of [SW98] is restricted to quasi-uniform meshes. However, we refer to [HJHUT14] for operator preconditioning for 2D BEM on graded meshes. The extension of the latter result to 3D is beyond the scope of the present paper.

2.7. Numerical computation of electrostatic capacity. As outlined in the introduction, the capacity of \( \Omega \) can be computed by
\[
\text{Cap}(\Omega) = \frac{1}{4\pi} \langle \phi, 1 \rangle_\Gamma, \text{ where } \phi \in H^{-1/2}(\Gamma) \text{ solves } V\phi = 1 \text{ on } \Gamma = \partial\Omega. \tag{15}
\]
This yields \( \text{Cap}(\Omega) = \frac{1}{4\pi} \langle V^{-1}1, 1 \rangle_\Gamma \), and ellipticity of \( V^{-1} \) guarantees \( \text{Cap}(\Omega) > 0 \). Let \( \Phi^{\text{dual}}_\ell \in \mathcal{P}^0(\mathcal{T}^{\text{dual}}_\ell) \) be the Galerkin approximation \( 10 \) of \( \phi = V^{-1}1 \), which is obtained by Algorithm 1 for \( f = 1 \). Then, a natural approximation of the capacity \( 15 \) is
\[
\text{Cap}_\ell(\Omega) := \frac{1}{4\pi} \langle \Phi^{\text{dual}}_\ell, 1 \rangle_\Gamma. \tag{16}
\]
We note that this approximation is controlled by the energy error.

**Proposition 4.** There holds \( 0 < \text{Cap}_\ell(\Omega) \leq \text{Cap}(\Omega) \) as well as
\[
\text{Cap}(\Omega) - \text{Cap}_\ell(\Omega) = \| \phi - \Phi^{\text{dual}}_\ell \|^2 \simeq \| \phi - \Phi^{\text{dual}}_\ell \|^2_{H^{-1/2}(\Gamma)}. \tag{17}
\]

**Proof.** Define \( 1^{\text{dual}}_\ell \in \mathbb{R}^{M_\ell} \) by \( 1^{\text{dual}}_\ell[j] = \langle 1, \chi^{\text{dual}}_{\ell,j} \rangle_\Gamma = |T^{\text{dual}}_{\ell,j}| > 0 \). Then, it holds that
\[
\Phi^{\text{dual}}_\ell = \sum_{j=1}^{M_\ell} x^{\text{dual}}_j \chi^{\text{dual}}_{\ell,j}, \text{ where } x^{\text{dual}}_\ell := (V^{\text{dual}}_\ell)^{-1} 1^{\text{dual}}_\ell.
\]
In particular, \( 4\pi \text{Cap}_\ell(\Omega) = 1^{\text{dual}}_\ell \cdot x^{\text{dual}}_\ell = 1^{\text{dual}}_\ell \cdot (V^{\text{dual}}_\ell)^{-1} 1^{\text{dual}}_\ell \). Since the matrix \( V^{\text{dual}}_\ell \) is symmetric and positive definite (and thus also its inverse \( (V^{\text{dual}}_\ell)^{-1} \)), it follows that \( \text{Cap}_\ell(\Omega) > 0 \). To see Eq. 17, recall that the combination of Eq. 9 and 10 yields the Galerkin orthogonality \( \langle V(\phi - \Phi^{\text{dual}}_\ell), \Psi^{\text{dual}}_\ell \rangle_\Gamma = 0 \) for all \( \Psi^{\text{dual}}_\ell \in \mathcal{P}^0(\mathcal{T}^{\text{dual}}_\ell) \). This leads to
\[
4\pi \left( \text{Cap}(\Omega) - \text{Cap}_\ell(\Omega) \right) = \langle \phi - \Phi^{\text{dual}}_\ell, 1 \rangle_\Gamma = \langle \phi - \Phi^{\text{dual}}_\ell, V\phi \rangle_\Gamma = \langle V(\phi - \Phi^{\text{dual}}_\ell), \phi - \Phi^{\text{dual}}_\ell \rangle_\Gamma = \| \phi - \Phi^{\text{dual}}_\ell \|^2 \geq 0.
\]
This proves Eq. 17 and, in particular, \( \text{Cap}_\ell(\Omega) \leq \text{Cap}(\Omega) \). \( \square \)
3. Numerical computations

In this section, we present some numerical computations that underpin our theoretical findings. In the experiments, we compare the performance of

- Algorithm 1 with Galerkin solution $\Phi^{\text{dual}}_\ell \in P^0(\mathcal{T}^{\text{dual}}_\ell)$ on the dual mesh and driven by the proposed ZZ-type estimator $\eta_\ell$,
- a standard adaptive algorithm (see Appendix A) from [FKMP13, FFK+14] with Galerkin approximation $\Phi_\ell \in P^0(\mathcal{T}_\ell)$ on the primal mesh $\mathcal{T}_\ell$ and driven by the weighted-residual error estimator,

for different adaptivity parameters $0 < \theta \leq 1$. One particular focus is on preconditioners, where we compare

- Algorithm 1 with its built-in operator preconditioning vs. diagonal preconditioning vs. non-preconditioning;
- Algorithm 5 with multilevel additive Schwarz preconditioning (MLAS) [FHPST18] vs. diagonal preconditioning [GM06] vs. non-preconditioning;

We consider lowest-order BEM for different polyhedral domains $\Omega$ starting from simple shapes, e.g., the unit cube (Section 3.1), and moving to more complicated shapes, e.g., a star-shaped domain (Section 3.3). If not stated otherwise, we employ Algorithm 1 with the Dörfler parameter $\theta = 1/2$ and operator preconditioning.

We emphasize that due to generic edge singularities, increasing the polynomial degree, without using anisotropic refinement, does not lead to any improved order of convergence. Usually one observes a slightly better constant, but the same overall algebraic rate; see, e.g., [FGH+16].

The numerical computations were done with help of Bempp, which is an open-source Galerkin boundary element library. We refer to [SBA+15, GBB+15, vWGBA15] for details on Bempp. A possible implementation of Algorithm 1 in Python with Bempp is given in Appendix B.

3.1. Example (Unit cube). We consider the unit cube $\Omega = (0,1)^3$, where a reference value of the capacity $\text{Cap}(\Omega)$ is known; see Figure 4. To our knowledge, the approximation $\text{Cap}(\Omega) \approx 0.66067815409957$ from [HP13, Table 1] with an error of order $10^{-13}$ is the best approximation available. This value is used to compute the capacity error $\text{err}_\ell := |\text{Cap} - \text{Cap}_\ell|$.

Figure 4. Example 3.1: Initial mesh $\mathcal{T}_0$ with 12 elements.

Figure 5 shows the convergence rates of the estimator $\eta^2_\ell$ and the capacity error $\text{err}_\ell$ plotted over the number of elements $\# \mathcal{T}_\ell$. For both adaptive algorithms, the error as well
as the estimator converge with rate $O(N^{-1})$. This underlines empirically that both error estimators are reliable and efficient, i.e., up to multiplicative constants equivalent to the error (i.e., $\eta^2 \simeq \text{err} = \| \phi - \Phi \|_2^2$). Although the empirical reliability constant $\text{err}/\eta^2_\ell$ is slightly better for Algorithm 5 and the residual estimator, Algorithm 1 and ZZ-type estimator lead to a smaller error for the capacity approximation. Figure 6 compares different values of the Dörfler marking parameter $\theta \in \{0.2, 0.4, 0.6, 0.8, 1\}$ in Algorithm 1, where $\theta = 1$ coincides with uniform mesh-refinement. We see that Algorithm 1 is robust and any choice of $\theta < 1$ leads to the optimal convergence behavior. Only uniform mesh-refinement ($\theta = 1$) leads to a sub-optimal rate $O(N^{-2/3})$. Table 1 displays some numerical results for the sequence of solutions produced by Algorithm 1. It shows that, e.g., Step 13 with 930 elements is sufficient to reach an accuracy of $5.520 \cdot 10^{-4}$. Such a computation can be done on a usual workstation within seconds.

![Figure 5](image-url)  
**Figure 5.** Example 3.1 Convergence of the error estimator $\eta^2_\ell$ and capacity error $\text{err}_\ell$. The estimator $\eta^2_\ell$ as well as the error converge with optimal order $O(N^{-1})$, if the a weighted-residual or the proposed ZZ-based error estimator is used.

![Table 1](table-url)  
**Table 1.** Example 3.1 Numerical results of Algorithm 1 for $\theta = 1/2$.  

**Figure 7** displays the condition number of the arising linear systems (10). We emphasize that the MLAS preconditioning is optimal in the sense that the condition number of the
Figure 6. Example 3.1: Convergence of the error estimator $\eta^2_\ell$ (circles) and capacity error $\text{err}_\ell$ (squares) for different value of $0 < \theta < 1$ and uniform refinement $\theta = 1$. Uniform refinement leads to a reduced rate of convergence.

arising systems remains bounded, independently of the number of elements; see [FHPS18]. This is confirmed for MLAS as well as empirically observed also for operator preconditioning with the hypersingular operator in Algorithm 1. On the other hand, the condition number of the non-preconditioned systems explodes with increasing number of elements resp. mesh graduation. Moreover, Figure 7 shows that diagonal preconditioning does lead to a slower growth of the condition number, but is not optimal. Figure 8 and Figure 9 show the distribution of the error estimator in some of the generated adaptive meshes. Due to generic edge singularities, the adaptive algorithm leads to refinement along edges and corners, while elements in the interior of the cube-facets stay relatively coarse.

3.2. Example 2: Fichera cube. As second example, we consider the Fichera cube $[-1,1]^3 \setminus [0,1]^3$ with side length 2; see Figure 11 (left). In contrast to the unit cube, we lack a highly accurate benchmark computation and approximate the capacity error by $\text{err}_\ell := |\text{Cap} - \text{Cap}_\ell| \approx |\text{Cap}_{\ell_{\text{max}}} - \text{Cap}_\ell|$ for all $0 \leq \ell < \ell_{\text{max}}$.

Convergence behaviour of the estimator $\eta^2_\ell$ and of the error $\text{err}_\ell$ are displayed in Figure 10. Both, Algorithm 1 as well as Algorithm 5 lead to the optimal rate of convergence $O(N^{-1})$. Table 2 shows some numerical results produced by Algorithm 1. For the fichera cube approximately $10^4$ elements are sufficient to achieve an error of order $10^{-4}$. This can be computed easily on a workstation within a couple of minutes. Figure 11 and Figure 12 show the distribution of the error estimator in some of the generated adaptive meshes. Due to generic edge singularities, the adaptive algorithm leads to refinement along edges and corners, while elements in the interior of the cube faces stay relatively coarse.
Figure 7. Example 3.1: Condition number for different preconditioning strategies for the arising linear systems in Algorithm 1 (ZZ) with operator preconditioning with the hypersingular operators vs. Algorithm (Res) with multilevel additive Schwarz preconditioning. Additionally, diagonal preconditioning is employed in both cases.

Figure 8. Example 3.1: Mesh $\mathcal{T}_\ell$ and distribution of the error estimator $\eta^2_\ell$ for $\ell = 10$ with 306 elements (left) and for $\ell = 15$ with 1244 elements (right).

3.3. Example 3: Star-shaped geometry. As third example, we consider a star-shaped geometry shown in Figure 13. We use Algorithm 1 as black-box method. Figure 14 shows the convergence of the estimator $\eta^2_\ell$ and the capacity error $\text{err}_\ell := |\text{Cap}_{\ell_{\text{max}}} - \text{Cap}_\ell| \approx |\text{Cap} - \text{Cap}_\ell|$. We observe the optimal convergence order $\mathcal{O}(N^{-1})$ for the estimator as well as the error for Algorithm 1 and Algorithm 5. The rate of convergence is robust with respect to the Dörfler marking parameter $0 < \theta \leq 1$. Besides uniform refinement ($\theta = 1$), all tested parameters $\theta \in \{0.2, 0.4, 0.6, 0.8\}$ lead to the same rate of $\mathcal{O}(N^{-1})$; see Figure 15.
Figure 9. Example 3.1: Mesh $T_\ell$ and distribution of the error estimator $\eta_\ell^2$ for $\ell = 20$ with 3792 elements (left) and for $\ell = 30$ with 46044 elements (right).

Figure 10. Example 3.2: Convergence of the error estimator $\eta_\ell^2$ and capacity error $\text{err}_\ell$. The estimator $\eta_\ell^2$ as well as the error converge with optimal order $O(N^{-1})$, if the weighted-residual or the proposed ZZ-based error estimator is used.
Figure 11. Example 3.2. Initial triangulation $\mathcal{T}_0$ (left) consisting of 48 triangles. Mesh $\mathcal{T}_\ell$ and distribution of the error estimator $\eta_\ell^2$ for $\ell = 5$ with 410 elements (right).

Figure 12. Example 3.2. Mesh $\mathcal{T}_\ell$ and distribution of the error estimator $\eta_\ell^2$ for $\ell = 10$ (left) with 1308 elements and $\ell = 15$ (right) with 4226 elements.

Figure 16 shows the condition number of the arising linear systems (10). Operator preconditioning with the hypersingular operator in Algorithm 1 as well as the multilevel additive Schwarz preconditioner guarantee a bounded condition number. On the other hand, diagonal- and non-preconditioning lead to an increasing condition number as the number of elements grows. Similarly to previous examples, the Algorithm has to resolve generic edge singularities. Figure 17 and Figure 18 show the distribution of $\eta_\ell^2$ on some meshes generated by Algorithm 1.

Table 3 shows some numerical results for the star-example. Algorithm 1 takes 22 steps and approximately $10^4$ elements to reach an error of order $10^{-4}$.

Appendix A. Weighted-residual error estimator

In this section, we briefly sketch the state of the art for adaptive BEM driven by the weighted-residual error estimator. We consider the model problem (8) with right-hand side $f \in H^1(\Gamma)$. Note that the additional regularity of $f$ (instead of only $f \in H^{1/2}(\Gamma)$) is required for the well-posedness of the weighted-residual error estimator introduced below. Here, $\mathcal{T}_\ell$ is a conforming triangulation of $\Gamma$ into plane (closed) surface triangles.
Figure 13. Example 3.3: Geometry and initial mesh $\mathcal{T}_0$ with 24 elements of the star example. The point of view is along the $z$-axis (left) and along the $y$-axis (right).

| step $\ell$ | number of elements $\#\mathcal{T}_\ell$ | $\text{Cap}_\ell$ | $\eta_\ell^2$ | $|\text{Cap}_{\ell_{\text{max}}} - \text{Cap}_\ell|$ |
|-------------|---------------------------------|-----------------|---------------|---------------------------------|
| 0           | 24                              | 0.2942967843    | 2.580 $\cdot 10^{-1}$ | 5.456 $\cdot 10^{-3}$ |
| 5           | 100                             | 0.2978622929    | 7.092 $\cdot 10^{-2}$ | 5.456 $\cdot 10^{-3}$ |
| 14          | 1136                            | 0.2995412185    | 1.384 $\cdot 10^{-2}$ | 1.686 $\cdot 10^{-3}$ |

| 34          | 194838                          | 0.2998587081    | 1.110 $\cdot 10^{-4}$ |                                   |

Table 3. Example 3.3: Numerical results of Algorithm 1 with $\theta = 1/2$.

Figure 14. Example 3.3: Convergence of the error estimator $\eta_\ell^2$ and capacity error $\text{err}_\ell$. The estimator $\eta_\ell^2$ as well as the error converge with optimal order $O(N^{-1})$, if a weighted-residual or the proposed ZZ-based error estimator is used.
The Lax–Milgram lemma guarantees existence and uniqueness of \( \Phi_\ell \in P^0(\mathcal{T}_\ell) \) such that
\[
\langle V\Phi_\ell, \Psi_\ell \rangle_\Gamma = \langle f, \Psi_\ell \rangle_\Gamma \quad \text{for all } \Psi_\ell \in P^0(\mathcal{T}_\ell).
\] (18)
Figure 17. Example 3.3: Mesh $T_\ell$ and distribution of the error estimator $\eta_\ell^2$ for $\ell = 10$ (left) with 360 elements and $\ell = 15$ (right) with 1524 elements.

Figure 18. Example 3.3: Mesh $T_\ell$ and distribution of the error estimator $\eta_\ell^2$ for $\ell = 20$ (left) with 5754 elements and $\ell = 25$ (right) with 20304 elements.

Unlike above, we note that the discrete solution is now computed on the primal triangulation instead of the dual triangulation. With $\nabla$ being the surface gradient, the local contributions of the weighted-residual error estimator read

$$
\mu_\ell(T) := \text{diam}(T)^{1/2} \| \nabla (f - V \Phi_\ell) \|_{L^2(T)} \quad \text{for all } T \in T_\ell,
$$

(19)

We note that reliability [CMS01] and efficiency [AFF+17] hold in the sense of

$$
(C'_{\text{rel}})^{-1} \| \phi - \Phi_\ell \|_{H^{-1/2}(\Gamma)} \leq \mu_\ell := \left( \sum_{T \in T_\ell} \mu_\ell(T)^2 \right)^{1/2} \leq C'_{\text{eff}} \| h_\ell^{1/2} (\phi - \Phi_\ell) \|_{L^2(\Gamma)},
$$

(20)

where the constants $C'_{\text{rel}}, C'_{\text{eff}} > 0$ depend only on $\Gamma$ and $\gamma$-shape regularity of $T_\ell$. As above, $h_\ell$ denotes the local mesh-size function $h_\ell|_T := \text{diam}(T)$ for all $T \in T_\ell$. Based on $\mu_\ell$, the standard adaptive algorithm from [FKMP13, Gan13, FFK+14] reads as follows:

**Algorithm 5. Input:** Initial conforming triangulation $T_0$ of $\Gamma$ into plane surface triangles, adaptivity parameters $0 < \theta \leq 1$ and $C_{\text{mark}} \geq 1$.

**Adaptive loop.** Iterate the following steps (i)–(iv) for all $\ell = 0, 1, 2, \ldots$:

(i) Compute the Galerkin solution $\Phi_\ell \in P^0(T_\ell)$ from (18).

(ii) Compute the local contributions $\mu_\ell(T)$ from (19) for all $T \in T_\ell$. 

18
(iii) Determine a set of, up to the multiplicative constant $C_{\text{mark}}$, minimal cardinality, which satisfies the Dörfler marking criterion
\[ \theta \sum_{T \in M_\ell} \mu(T)^2 \leq \mu_\ell^2. \]
(iv) Use NVB and refine all marked elements $T \in M_\ell$ to obtain $T_{\ell+1} := \text{refine}(T_\ell, M_\ell)$.

**Output:** Sequence of successively refined triangulations $T_\ell$ as well as corresponding Galerkin solutions $\Phi_\ell \in P^0(T_\ell)$ and weighted-residual error estimators $\mu_\ell$.

The following theorem is the main result from [FKMP13 Gan13 FFK+14]:

**Theorem 6.** For all $0 < \theta \leq 1$, there exist constants $C_{\text{lin}} > 0$ and $0 < q_{\text{lin}} < 1$ such that the output of Algorithm 7 is linearly convergent in the sense of
\[ \eta_{\ell+n} \leq C_{\text{lin}}^{q_{\text{lin}}} \eta_\ell \quad \text{for all } \ell, n \in \mathbb{N}_0. \]  
Moreover, there exists a constant $0 < \theta_{\text{opt}} < 1$ such that for all $0 < \theta < \theta_{\text{opt}}$, the output of Algorithm 5 converges with the optimal algebraic rate in the following sense: For all $s > 0$, define
\[ A_s(\phi) := \sup_{N \geq \# T_0} \min_{T_\ell \in \text{refine}(T_0)} \min_{N^* \mu_{\text{opt}} \in [0, \infty]} N^* \mu_{\text{opt}} \leq C_{\text{opt}} A_s(\phi), \] where $\text{refine}(T_0)$ denotes the set of all possible NVB refinements of $T_0$ and $T_\ell$ corresponds to the estimator $\mu_{\text{opt}}$. Then, there exists constants $c_{\text{opt}}, C_{\text{opt}} > 0$ such that
\[ c_{\text{opt}}^{-1} A_s(\phi) \leq \sup_{\ell \in \mathbb{N}_0} (\# T_\ell)^s \mu_\ell \leq C_{\text{opt}} A_s(\phi), \]
i.e., Algorithm 5 asymptotically realizes (and even characterizes) each possible algebraic convergence rate $s > 0$ and therefore converges with the optimal rate. The constants $C_{\text{lin}}$ and $q_{\text{lin}}$ depend only on $\Gamma, \gamma$-shape regularity for $T_0$, and $\theta$. While $c_{\text{opt}}$ is generic, $C_{\text{opt}}$ depends only on $T_0$, $C_{\text{lin}}, q_{\text{lin}}, C_{\text{mark}}$, and $s$. \hfill \Box

**Remark 7.** The recent work [FHP18] proves that Theorem 6 remains valid, if (18) is solved inexactly by PCG with optimal additive Schwarz preconditioner. With the PCG iterates $\Phi_{\ell,k} \approx \Phi_\ell$, the iterative solver is stopped if $\|\Phi_{\ell,k-1} - \Phi_{\ell,k}\|_{} \leq \lambda \mu_\ell(\Phi_{\ell,k})$, where the residual error estimator is evaluated at $\Phi_{\ell,k}$ instead of the exact Galerkin solution. Then, linear convergence (21) holds for any $\lambda > 0$, while optimal rates require $\lambda \ll 1$ to be sufficiently small.

To empirically measure the performance of Algorithm 1 in the numerical experiments of Section 3 we consider the output of Algorithm 5 for $f = 1$ as benchmark.

**Corollary 8.** Consider the output of Algorithm 5 for $f = 1$ and arbitrary $0 < \theta \leq 1$ and $C_{\text{mark}} \geq 1$. Define the discrete capacity
\[ \text{Cap}_\ell(\Omega) := \frac{1}{4\pi} \langle \Phi_\ell, 1 \rangle_\Gamma. \]
Then, there holds (17) as well as monotonicity $0 < \text{Cap}_\ell(\Omega) \leq \text{Cap}_{\ell+1} \leq \text{Cap}(\Omega)$ for all $\ell \in \mathbb{N}_0$ and, in particular, convergence
\[ 0 \leq \text{Cap}(\Omega) - \text{Cap}_\ell(\Omega) \leq C_{\text{cap}} \mu_\ell^2 \rightarrow 0 \quad \text{as } \ell \rightarrow \infty. \] Moreover, if $0 < \theta < \theta_{\text{opt}}$ is sufficiently small in the sense of Theorem 6, it follows that
\[ 0 \leq \text{Cap}(\Omega) - \text{Cap}_\ell(\Omega) \leq C_{\text{cap}}' A_s(\phi)^2 (\# T_\ell)^{-2s} \quad \text{for all } \ell \in \mathbb{N}_0. \] The constant $C_{\text{cap}}'$ depends only on $\Gamma$ and $\gamma$-shape regularity of $T_\ell$, and $C_{\text{cap}}' := C_{\text{cap}} C_{\text{opt}}'$ with $C_{\text{opt}}'$ from Theorem 6.
Proof. Arguing as in the proof of Proposition 4 we see that
\[ 0 < \text{Cap}'(\Omega) \leq \text{Cap}(\Omega) \quad \text{as well as} \quad 0 \leq \text{Cap}(\Omega) - \text{Cap}'(\Omega) \simeq \|\phi - \Phi_\ell\|_{H^{-1/2}(\Gamma)}^2. \]
Therefore, (24)–(25) are immediate consequences of Theorem 6 and reliability (20). Overall, it only remains to prove monotonicity \( \text{Cap}'(\Omega) \leq \text{Cap}'(\Omega) + 1 \) for all \( \ell \in \mathbb{N}_0 \): Note that \( \mathcal{P}^0(\mathcal{T}_\ell) \subseteq \mathcal{P}^0(\mathcal{T}_{\ell+1}) \), which fails for the sequence of dual triangulations, i.e., \( \mathcal{P}^0(\mathcal{T}_{\ell+1}^\text{dual}) \supseteq \mathcal{P}^0(\mathcal{T}_{\ell+1}) \). With this additional nestedness, it holds that \( \Phi_{\ell+1} - \Phi_\ell \in \mathcal{P}^0(\mathcal{T}_{\ell+1}) \). Therefore, there holds the discrete Galerkin orthogonality \( \langle V(\Phi_{\ell+1} - \Phi_\ell), \Psi_{\ell+1}\rangle_\Gamma = 0 \) for all \( \Psi_{\ell+1} \in \mathcal{P}^0(\mathcal{T}_{\ell+1}) \). This implies the Pythagoras theorem
\[ \|\phi - \Phi_\ell\|^2 = \|\phi - \Phi_{\ell+1}\|^2 + \|\Phi_{\ell+1} - \Phi_\ell\|^2 \]
with respect to the energy norm. Arguing as for the proof of (17), we thus see that
\[ 4\pi \left( \text{Cap}_{\ell+1}(\Omega) - \text{Cap}_\ell(\Omega) \right) = \|\Phi_{\ell+1} - \Phi_\ell\|^2 \geq 0. \]
This concludes the proof. \( \square \)

Finally, we refer to [FFK+15] for the extension of Theorem 6 to the hypersingular operator associated with the Laplace problem and to [BBHP19] for optimality in the case of the Helmholtz equation. The work [FCH+16] gives a first mathematical proof of optimal algebraic convergence rates for the point-wise approximation of the PDE-solution via BEM and potential operators. Moreover, [FPvdZ16] generalizes the latter approach to general goal-oriented adaptivity with linear goal functional.

**Appendix B. Implementation with Bempp**

The following code demonstrates a possible implementation of Algorithm 1 in Python with the Bempp library. The demonstration code can also be downloaded from the Bempp homepage [https://bempp.com](https://bempp.com).

```python
import bempp.api
import numpy as np

max_el = 600000 # max number elements
step_counter = 0
theta = 0.5 # marking parameter
grid = bempp.api.shapes.cube(h=0.1) # import initial grid

# initialize function for the right-hand side
def one_fun(x, n, domain_index, res):
    res[0] = -1

# Adaptive loop
while (grid.leaf_view.entity_count(0) <= max_el):
    step_counter += 1
    bary_grid = grid.barycentric_grid() # barycentric refinement

# initialize function spaces
const_space = bempp.api.function_space(grid, 'DP', 0)
lin_space = bempp.api.function_space(grid, 'P', 1)
bary_const_space = bempp.api.function_space(bary_grid, 'DP', 0)
bary_lin_space = bempp.api.function_space(bary_grid, 'DP', 1)

# initialize operators
base_slp = bempp.api.operators.boundary.laplace.single_layer(bary_space, bary_space, bary_space)
slp, hyp = bempp.api.operators.boundary.laplace.single_layer_and_hypersingular_pair(grid, spaces='dual', base_slp=base_slp, stabilization_factor=1)
rank_one_op = bempp.api.RankOneBoundaryOperator(hyp.domain, hyp.range, hyp.dual_to_range)
hyp_regularized = hyp + rank_one_op
```
## initialize right-hand side

```python
rhs_fun = bempp.api.GridFunction(slp.range, fun=one_fun)
```

## initialize preconditioned lhs

```python
lhs = slp * hyp_regularized
discrete_op = lhs.strong_form()
```

## solve via GMRES

```python
from scipy.sparse.linalg import gmres
def callback(x):
    global number_of_iterations
    number_of_iterations += 1

phi_vec, info = gmres(discrete_op, rhs_fun.coefficients, tol=1e-10, callback=callback)
phi_fun = hyp_regularized * bempp.api.GridFunction(hyp.domain, coefficients=phi_vec)

print("Number of iterations: (0)".format(number_of_iterations))
```

## compute the capacity

```python
capacity = -phi_fun.integrate()[0,0]
print("The capacity is (0)".format(capacity))
```

## compute the error estimator

```python
bary_map = grid.barycentric_descendants_map()
bary_index_set = bary_grid.leaf_view.index_set()

# create sorted list of elements
index_set = grid.leaf_view.index_set()
elements = grid.leaf_view.entity_count(0) * [None]
for element in grid.leaf_view.entity_iterator(0):
    elements[index_set.entity_index(element)] = element

local_est_bary = np.zeros(bary_grid.leaf_view.entity_count(0), dtype='float64')
local_est = np.zeros(grid.leaf_view.entity_count(0), dtype='float64')
new_space = bempp.api.function_space(grid, "B-P", 1)

map_dual_to_bary = bempp.api.operators.boundary.sparse.identity(
    phi_fun.space, bary_lin_space, bary_lin_space)
map_lin_to_bary_lin = bempp.api.operators.boundary.sparse.identity(
    new_space, bary_lin_space, bary_lin_space)

# interpret function values on dual elements as node-values in S^1
Iphi_coefficients = phi_fun.coefficients
Iphi = bempp.api.GridFunction(new_space, coefficients=Iphi_coefficients)

# lift both functions to P^1(T_l.bary)
phi = map_dual_to_bary * phi_fun
Iphi_lin_bary = map_lin_to_bary_lin * Iphi

zz_diff = phi - Iphi_lin_bary

# compute the L^2-norm in each barycentric element
for element in bary_grid.leaf_view.entity_iterator(0):
    index = bary_index_set.entity_index(element)
    local_est_bary[index] = zz_diff.l2_norm(element)**2

# add up all barycentric contributions for each primal element
for m in range(bary_map.shape[0]):
    element = grid.leaf_view.element_from_index(m)
    mesh_size = element.geometry.volume
for n in range(bary_map.shape[1]):
    local_est[m] += local_est_bary[bary_map[m, n]]
local_est[m] = local_est[m]*mesh_size**(1./2) #scale with primal mesh-size

total_est = np.sum(local_est)

print("Squared ZZ-Estimator: {0}".format(total_est))

## Doerfler-Marking and refining
idx = np.argsort((-1)*local_est)
ind_on_marked =0
counter = 0

while (ind_on_marked < theta * total_est):
    ind_on_marked += local_est[idx[counter]]
    grid.mark(elements[idx[counter]])
    counter += 1

grid = grid.refine() # refine grid
print("New number of elements {0}".format(grid.leaf_view.entity_count(0)))
